Abstract: A combination of hematoma aspiration and local delivery of chemicals may be more effective than either therapy in intracerebral hemorrhage (ICH). The aim of the present study was to develop a rat model of hematoma aspiration plus intralesional injection after ICH. ICH was induced in adult Sprague-Dawley rats by an intrastrital injection of bacterial collagenase IV. Hematoma aspiration was performed 3.5 h after ICH onset. Following aspiration, normal saline was injected into the lesion cavity. Hematoma aspiration with or without subsequent saline injection significantly reduced the hematoma volume, lesion volume, and perihematomal neutrophil infiltration. Hematoma aspiration plus subsequent intralesional injection is simple, feasible, and safe. This ICH model can be used to assess the effectiveness of hematoma removal plus local delivery of chemicals.

Key words: animal model, hematoma aspiration, intracerebral hemorrhage, intralesional injection, rat

Introduction

Intracerebral hemorrhage (ICH) is usually caused by rupture of a cerebral vessel or aneurysm [18]. ICH is the least treatable type of stroke and a major public health problem, affecting two million people worldwide each year [23]. Management of ICH is largely supportive, and the outcome remains poor [3, 7, 28]. Several therapeutic approaches for ICH are being evaluated, including stereotactic minimally invasive aspiration, neuroprotective drugs, and neural stem cell transplantation. Clinical trials addressing a single pathogenic factor, such as hemorrhage volume or hematoma enlargement, have been successfully conducted, but clinical benefit cannot be shown [12, 13, 15, 18]. The negative results suggest that a combination of hematoma removal and local delivery of chemicals may be more effective [26].

Hematoma removal may alleviate the mass effect, lessen the damage caused by release of lysed blood products, and prevent the secondary pathological processes. The European Stroke Initiative Guidelines recommend stereotactic minimally invasive methods to remove a deep hematoma within 12 h of ICH onset [22]. A trial of stereotactic treatment of intracerebral hematoma by means of a plasminogen activator reported a significant reduction in the hematoma volume by 10–20% via ste-
Nevertheless, there was no difference in survival at 180 days. Our current knowledge concerning the potential benefit of a combination of hematoma aspiration and local delivery of chemicals is limited partly because of a lack of suitable animal models. The purpose of this study was to establish a rat model incorporating stereotactic minimally invasive aspiration plus intralesional injection using an established ICH model [19].

Materials and Methods

Subjects and experimental groups
Experimental protocols were approved by the Committee on the Use of Live Animals in Teaching and Research, the University of Hong Kong. A total of 67 male Sprague-Dawley (SD) rats, 11–13 weeks old and weighing between 400 and 500 g, were used in this study. They were provided by the Laboratory Animal Unit, the University of Hong Kong, and were reared in a temperature-controlled room with standard chow and water supply. The rats were divided into 3 groups: the ICH only group (n=20), with induction of ICH and sham hematoma aspiration; the aspiration only group (n=26), with induction of ICH and subsequent hematoma aspiration; and the saline group (n=21), with induction of ICH, hematoma aspiration, and intralesional injection of saline. Hematoma volume, lesion volume, and brain swelling were assessed 1 day after ICH induction. Histological analysis was performed 3 days after ICH induction. Prior to sacrifice, functional deficits were assessed by a blinded observer.

Intracerebral hemorrhage
Experimental ICH was induced via an intrastriatal injection of type IV collagenase [11, 17]. In brief, the rat was anesthetized using an intraperitoneal (i.p.) injection of sodium pentobarbital (55 mg/kg) and placed in a stereotaxic frame. A burr hole with a diameter of 2 mm was drilled along the left coronal suture at 3.0 mm lateral to the bregma. A 30-gauge (G) needle was inserted into the left striatum with its tip at 0.2 mm anterior to the bregma, 3 mm lateral to the midline, and 6 mm underneath the dural surface. ICH was induced by a slow injection of 0.2 U collagenase IV (Sigma-Aldrich, St. Louis, MO, USA) in 1.0 µl saline into the left striatum over 10 min. After injection, the needle was left in place for 5 min. The burr hole was sealed with bone wax, and the incision was sutured. Rectal temperature was maintained around 37 ± 0.5°C using a rectal thermostat probe and a thermostatically regulated heating pad (DC Temperature Control System, FHC Inc., Bowdoin, ME, USA). The right femoral artery was cannulated with a PE-50 catheter (Portex Ltd., Hythe, UK) for monitoring of arterial blood pressure and heart rate using a Power-Lab 16/35 Data Acquisition Systems (AD Instruments, Milford, MA, USA) as well as for measurement of blood glucose levels.

Hematoma aspiration plus intralesional injection
In order to determine the best time for hematoma aspiration, three different time points were studied: 2, 3.5, and 6 h after collagenase injection. The rats were randomly allocated to one of the above-mentioned time points (n=4 per time point). In brief, the rats were reanesthetized with pentobarbital (55 mg/kg, i.p.) and placed in a stereotactic frame. Aspiration was accomplished by gentle suction with a syringe attached to a 23-G needle placed at the center of the hematoma. Four attempts were made over 15 min. Care was taken to avoid blockade of the needle by the hematoma or bone wax. The volume of aspirated blood was measured using a 100 µl pipette. The aspirated blood was smeared onto SuperFrost Plus slides (Menzel-Glaser, Braunschweig, Germany). After fixation, the slides were stained with hematoxylin and eosin (HE) and then examined under a microscope.

Hematoma aspiration at 3.5 h after ICH was used in subsequent experiments. The saline injection group received 20 µl saline via a 25-G needle at an infusion rate of 500 µl per hour immediately following hematoma aspiration. In the ICH only group, a 23-G needle was placed at the center of the hematoma for 4 attempts over 15 min without any suction attempts. After injection or sham injection, the burr hole was sealed with bone wax, and the incision was sutured.

Hematoma volume
Hematoma volume was quantified at 24 h using a spectrophotometric assay [5, 10, 17]. In brief, hemispheric brain tissue minus the olfactory bulbs and cerebellum was acquired following transcardial perfusion. The tissue was homogenized in 3 ml 0.01 M PBS, and this was followed by 1 min of sonication on ice. After centrifugation at 12,000 g for 30 min, 100 µl supernatant was reacted with 400 µl Drabkin’s reagent (Sigma-Al-
ich drich) for 15 min. The absorbance reading minus the background reading at 540 nm was determined with a spectrophotometer (BioTek Instruments Inc., Winooski, VT, USA). Using a previously determined curve from known hemoglobin contents, the hematoma volume in the perfused brain was quantified.

**Lesion volume**

Rats were sacrificed 1 day after ICH induction to determine lesion volume. In brief, the rats were deeply anesthetized with sodium pentobarbital (80 mg/kg, i.p.) and perfused transcardially with saline and then 4% paraformaldehyde in 0.1 M phosphate buffer (PB) for 20 min. The brain was sliced into 1 mm-thick coronal slices. Images of the brain slices were taken using a digital camera and analyzed with the ImageJ software (National Institutes of Health, Bethesda, MA, USA) by a blinded observer. Lesion volume was calculated by the lesion area of each slice multiplied by the slice thickness [2].

**Tissue preparation and immunohistochemical analysis**

Rats were deeply anesthetized with sodium pentobarbital (80 mg/kg, i.p.) 3 days after ICH induction and perfused transcardially with saline and then 4% paraformaldehyde in 0.1 M PB for 20 min. The brain was post-fixed in 4% paraformaldehyde overnight at 4°C before being placed in 0.1 M PB containing 30% sucrose. Brain sections at 30 µm were obtained between 3 mm anterior to the bregma and 4 mm posterior to the bregma using a cryostat at −18°C. Brain sections were affixed on SuperFrost Plus slides, air-dried overnight, and stored for immunohistochemical (IHC) studies.

After blocking with 10% normal goat serum in phosphate buffered saline (PBS), the brain sections were incubated with the primary antibodies at 4°C overnight. Neutrophils were detected with rabbit anti-myeloperoxidase (MPO, 1:200, Dako, Glostrup, Denmark). The brain sections were then rinsed and incubated with biotinylated goat anti-rabbit antibody (1:200, Vector, Burlingame, CA, USA) for 2 h. Avidin-biotin complex solution was used to amplify the IHC signal, which was visualized using diaminobenzidine as the chromogen. Finally, the brain sections were coverslipped for examination under a light microscope.

**Behavioral test**

Rats were subjected to a modified limb placing test (MLPT) 1 day, 3 days, 7 days, and 2 weeks after ICH by a blinded observer [21]. Firstly, the rats were suspended at 10 cm above a table, and the stretch of the forelimbs toward the table was scored as follows: 0 point for normal stretch and 1 point for abnormal flexion. Next, the rats were positioned along the table edge, and their forelimbs were suspended over the edge and allowed to move freely. Each limb (forelimb, second task; hind limb, third task) was pulled down gently, and the retrieval and placement were checked. Finally, the rats were placed toward the table edge to check for lateral placement of the forelimbs. The last three tasks were scored in the following manner: 0 point for normal performance, 1 point for performance with a delay (2 s) or incomplete performance, and 2 points for no performance. A score of seven points indicates maximal neurological deficit, and a score of 0 point indicates normal performance.

**Statistical analysis**

All numerical values are expressed as the mean ± standard deviation. Data were analyzed with a two sample t-test or one-way analysis of variance followed by Turkey’s test, as appropriate. A *P* value of 0.05 or less was taken to infer statistical significance.

**Results**

**Physiological parameters**

There were no significant differences among the ICH only group, aspiration only group, and saline group with regard to body weight (data not shown), blood pressure, heart rate, rectal temperature, and blood glucose levels upon induction of ICH (Table 1).

**ICH plus hematoma aspiration**

Intrastriatal injection of 0.2 U collagenase IV caused a medium-sized hematoma. It was generally restricted to the dorsolateral striatum (caudate putamen and globus pallidus; Fig. 1). The hematoma could be aspirated 2 h (n=4) and 3.5 h (n=4) but not 6 h (n=4) after onset of ICH. The volume of aspirated blood ranged from 20 to 40 µl. HE staining of the aspirated blood showed red blood cells, neutrophils, and islands of fragmented striatum (Fig. 2).

**Hematoma volume and lesion volume**

Following hematoma aspiration at 3.5 h after onset, saline was injected into the lesion in the saline group.
One day after ICH induction, the brain of both the aspiration only group and saline group had a cavity within the center of the lesion (Fig. 1). The hematoma volume was 29.3 ± 1.7 µl in the ICH only group (n=5), 20.7 ± 3.1 µl in the aspiration only group (n=5) and 19.9 ± 4.0 µl in the saline group (n=5). The hematoma volume was significantly reduced by aspiration (Fig. 3). However, it was not significantly different between the aspiration only group and saline group. The lesion volume was 31.5 ± 3.5 µl in the ICH only group (n=5), 24.4 ± 5.7 µl in the aspiration only group (n=6), and 21.6 ± 4.2 µl in the saline group (n=5). The lesion volume was significantly reduced by aspiration but not further reduced by saline injection (Fig. 3).

**Neutrophil infiltration**

MPO staining revealed a high density of immunopositive cells within and around the hemorrhagic lesion 3 days after ICH induction (Fig. 4). Aspiration of the hematoma reduced the number of MPO-positive cells in
the perihematomal area when compared with the ICH only group (409.0 ± 60.2 cells/mm², n=4), and the number of MPO-positive cells was similar in both the aspiration only group (158.0 ± 71.5 cells/mm², n=4) and saline group (119.6 ± 60.5 cells/mm², n=4, Fig. 4).

Functional deficit

All rats survived the surgery and completed the behavioral test. The rats developed significant limb placing deficits 1, 3, 7, and 14 days after ICH induction. Hematoma aspiration did not affect the behavioral outcome at all time points (Fig. 5). The respective MLPT scores were 6.8 ± 0.3, 6.9 ± 0.2, 6.4 ± 0.5, and 5.6 ± 0.5 in the ICH only group (n=5), 6.8 ± 0.3, 6.6 ± 0.3, 6.5 ± 0.3, and 6.1 ± 0.1 in the aspiration only group (n=5), and 6.9 ± 0.2, 6.7 ± 0.2, 6.5 ± 0.5, and 6.0 ± 0.7 in the saline group (n=6).

**Discussion**

This study successfully established a rat ICH model incorporating hematoma aspiration plus intralesional injection. Following hematoma aspiration, intralesional injection is a simple and feasible procedure. The hematoma was aspirated 3.5 h after ICH onset without using a thrombolytic drug. Hematoma aspiration and/or saline injection reduced the hematoma volume, lesion volume, and perihematomal neutrophil infiltration in the rat.

In a previous study, ICH was induced by collagenase injection, and streptokinase was locally administered at 4 h after ICH onset to lyse the hematoma to permit hematoma aspiration at 5 h after ICH onset [1]. Slight improvement of global behavior was observed at 4 weeks after hematoma aspiration, but there was no significant difference in the skilled forelimb function at 7 weeks. The use of thrombolytic agents to lyse the hematoma is being investigated [14], and the adverse effects of thrombolytic agents on the brain parenchyma and vasculature are our concerns [9, 25, 27]. In the present study, hematoma aspiration was performed without using a thrombolytic agent, and intralesional injection of saline was performed. Without using any thrombolytic agent, the hematoma could be aspirated between 2 and 3.5 h after collagenase injection, and aspiration was not feasible 6 h after ICH onset. This finding is consistent with blood clotting within 4 h after collagenase injection in the rat [6]. In clinical practice, it is likely that hematoma aspiration is feasible for a few hours after ICH onset prior to clot formation.

To maintain minimal disturbance of the intracranial pressure (ICP), a volume of saline of around two thirds of the original hematoma volume, i.e., 20 µl, was injected into the lesion immediately following hematoma aspiration. Although the ICP was not measured directly,
there were no significant differences in blood pressure and heart rate among the three groups.

In our study, we used normotensive rats, and hematoma aspiration significantly reduced the hematoma volume. However, this may not be the case clinically since hypertension is the most important risk factor for ICH [4]. Our previous study showed that elevated blood pressure increased the hematoma volume in rats [20]. Therefore, the effects of hematoma aspiration in hypertensive ICH rats need to be studied in the future.

Inflammation occurs after ICH and is characterized by infiltration of neutrophils and macrophages as well as activation of microglia [8]. Both the hematoma and damaged brain tissue liberate chemotactic factors, including thrombin, which attract neutrophils from the blood stream to migrate into the brain tissue around the hematoma [16]. In the present study, hematoma aspiration significantly lessened the toxic blood components. Thus, neutrophil infiltration in the perihematomal area was reduced following hematoma aspiration. Nevertheless, the reduction in hematoma volume, lesion volume, and neutrophil infiltration did not translate into functional improvement up to 14 days after ICH induction. It is possible that incorporation of another treatment strategy or a greater reduction in lesion volume is needed to achieve a functional benefit. In addition, a longer period of observation may be required. Finally, the surgical aspiration was performed over 15 min via a burr hole; the adverse effects of local injury by this burr-hole stereotaxic aspiration on the perifocal or diffuse brain edema and the functional score need to be studied in the future.

In summary, hematoma aspiration plus intralesional injection is a simple, minimally invasive technique that can be performed without craniotomy. This model may be useful for evaluation of combinational treatment strategies in ICH. Early removal of the hematoma not only lessens this detrimental factor but also gives room for local administration of a neuroprotective agent.
